## ABSTRACT

We have used new astrometric and spectroscopic observations to refine the volume-complete sample of M dwarfs defined in previous papers in this series. With the addition of Hipparcos astrometry, our revised VC<sup>2</sup> sample includes 558 main-sequence stars in 448 systems. Analysis of that dataset shows no evidence for any systematic kinematic bias. Combining those data with an Hipparcos-based sample of AFGK dwarfs within 25 parsecs of the Sun, we have derived the Solar Neighbourhood luminosity function,  $\Phi(M_V)$ , for stars with absolute magnitudes between -1 and +17. Using empirical and semi-empirical mass- $M_V$  relations, we transform  $\Phi(M_V)$  to the present-day mass function,  $\psi(M)$  ( $\frac{dN}{dM}$ ). Depending on the mass-luminosity calibration adopted,  $\psi(M)$  can be represented by either a two-component or three-component power-law. In either case, the

power-law index,  $\alpha$ , has a value of  $\sim 1.3$  at low masses ( $0.1 < \frac{M}{M_\odot} < 0.7$ ), and the local mass density of main sequence stars is  $\sim 0.031 M_\odot \text{pc}^{-3}$ .

We have converted  $\psi(M)$  to an estimate of the initial mass function,  $\Psi(M)$ , by allowing for stellar evolution, the density law perpendicular to the Plane and the local mix of stellar populations. The results give  $\alpha = 1.1$  to  $1.3$  at low masses, and  $\alpha = 2.5$  to  $2.8$  at high masses, with the change in slope lying between  $0.7$  and  $1.1 M_\odot$ .

Finally, the (U, W) velocity distributions of both the VC<sup>2</sup> sample and the fainter ( $M_V > 4$ ) stars in the Hipparcos 25-pc sample are well-represented by two-component Gaussian distributions, with  $\sim 10\%$  of the stars in the higher velocity-dispersion component. We suggest that the latter component is the thick disk, and offer a possible explanation for the relatively low velocity dispersions shown by ultracool dwarfs.

*Subject headings:* (Galaxy:) solar neighborhood — stars: kinematics — stars: luminosity function, mass function

## 1. Introduction

The nearest stars represent an important tool in studies of Galactic structure, since they provide an opportunity for detailed analysis of constituent members of the various stellar populations and sub-populations. This holds particularly for M dwarfs, which account for the overwhelming majority of stars currently present in the Galaxy. With a local density of  $\sim 0.07 \text{ pc}^{-3}$ , these stars are ideal tracers of many properties of the Galactic disk. Until recently, the main limitation in such analyses was the lack of basic observational data, such as spectral types or radial velocities. Our main goal in undertaking the Palomar/Michigan State University (PMSU) survey (Reid, Hawley & Gizis, 1995, PMSU1; Hawley, Gizis & Reid, 1996, PMSU2; Hawley, Gizis & Reid, 1997), was to remedy this defect by compiling moderate resolution spectroscopy for all M dwarfs in the preliminary version of the third Catalogue of Nearby Stars (Gliese & Jahreiß, 1991; pCNS3). We obtained observation of over 2000 candidate M dwarfs, omitting only unresolved binary companions. Calculating distances by combining spectroscopic parallaxes with the then-available trigonometric data, we defined  $M_V$ -dependent distance limits which isolate a volume-complete sample, and used

---

<sup>1</sup>Based partly on observations made at the 60-inch telescope at Palomar Mountain which is jointly owned by the California Institute of Technology and the Carnegie Institution of Washington

that sample to derive estimates of the luminosity function and the velocity distribution of low mass stars (PMSU1), in addition to studying the range of chromospheric activity (PMSU2).

Since the completion of our initial analysis, two major new datasets have become available. First, the Hipparcos catalogue has been published (ESA, 1997), including milliarcsecond-accuracy astrometry for over 110,000 stars brighter than 13th magnitude. Almost two-thirds of the stars in the pCNS3 have observations by Hipparcos. Second, as a follow-up to PMSU, we obtained echelle spectroscopy of many of the brighter M dwarfs in the pCNS3, including all of the stars in the volume-complete sample defined in PMSU1. Those data are now fully analysed, and presented by Gizis, Reid & Hawley (2002; PMSU3). The high-resolution observations provide significantly more accurate radial velocities, besides more sensitive measurement of chromospheric activity.

Both of these new datasets have potential importance for the results of the analysis presented in PMSU1. Revising the distances of a substantial number of stars affects both the composition of the volume-complete sample and the derived tangential motions, while the new radial velocity determinations affect the space motion determinations. We have therefore re-analysed the PMSU dataset, incorporating the new observational data. Section 2 describes the definition of the revised volume-complete sample; section 3 considers the effect on the luminosity function; section 4 rederives the mass function for nearby stars, combining our data with an Hipparcos 25-parsec sample of earlier-type main-sequence stars; and section 5 re-analyses the kinematics. The main results are summarised and discussed in section 6.

## 2. A volume-complete sample of Solar Neighbourhood M dwarfs

In PMSU1, we used the available trigonometric and photometric parallax information, together with our own distance estimates based on the ( $M_V$ , TiO5) calibration, to construct a volume-complete (VC) subset of the M dwarfs in the pCNS3. Over 2300 pCNS3 stars have Hipparcos astrometry, but, with incomplete sampling between  $V=8$  and the Hipparcos limit of  $V=13$ , that dataset includes only 712 M dwarfs from PMSU1 and PMSU2. Coverage is better amongst the brighter stars in the PMSU1 VC subset, however, with data for 330 of the 499 systems.

Figure 1 compares pre- and post-Hipparcos distance measurements for PMSU stars; there is a systematic shift towards higher distances (parallaxes tend to be overestimated, hence the Lutz-Kelker bias), and a significant number of M dwarfs move beyond the 25 parsec boundary of the pCNS3. Seventy-one of the 499 systems in the VC sample have revised

distances which place the stars beyond the completeness limits adopted for the appropriate absolute magnitude. We have therefore re-analysed the pCNS3 dataset, augmented by new observations, and derive a revised volume-complete sample of M dwarfs, (VC<sup>2</sup>).

## 2.1. Re-defining the sample

We have used the techniques described in PMSU1 to analyse the post-Hipparcos pCNS3 dataset, re-deriving the appropriate distance limits as a function of absolute magnitude. As before, we limit analysis to the 1684 M dwarf systems in the northern sample,  $\delta > -30^\circ$ , and set absolute magnitude limits  $8 \leq M_V \leq 16$ . Figure 2 provides the justification for our choice of distance limits, plotting the run of density ( $\rho_{sys}$ , number of *systems* per unit volume) with increasing distance; the distance limits,  $d_{lim}$ , are set where  $\rho_{sys}$  flattens, before the downturn due to incompleteness. Applying Schmidt’s (1968)  $V/V_{max}$  estimator to the same issue gives identical results.

As Table 1 shows, the revised distance limits match those derived in PMSU1, with the exception of the  $M_V=9.5$  bin, where  $d_{lim}$  decreases by 10%. A total of 545 stars in 435 systems, including 300 with Hipparcos data, meet these distance criteria. This dataset includes additional companions identified by Reid & Gizis (1997, RG97), Delfosse *et al.* (1999) and Beuzit *et al.* (2001). Only 16 systems lack PMSU3 echelle observations, and the majority (381 systems) have distances derived from trigonometric parallaxes. The relevant data for each stellar system are listed in Table 2, where we also give the proper motions and space velocities.

Besides providing improved distance estimates for stars already known to lie within the immediate Solar Neighbourhood, Hipparcos also identified a number of previously-unrecognised nearby stars. The full catalogue lists 78 stars which are not in the pCNS3, but have  $\pi_H > 45$  milliarcseconds (mas) or  $r < 22$  parsecs. Of these, 23 have formal absolute magnitude values in the range  $8 \leq M_V \leq 16$ . Ten of the latter subset, however, have spectral types which are clearly inconsistent with the inferred absolute magnitude; for example, HIP 21000, or BD+4:701A, has  $\pi_H = 84.8$  mas and an inferred  $M_V = 9.5$ , but spectral type F8. All ten are in binary systems, and the companion has influenced the astrometric results listed in the Hipparcos catalogue. This is a well known problem, which can be rectified through more sophisticated analysis; thus, Fabricius & Makarov (2000) derive  $\pi_{H'} = 4.2$  mas for HIP 21000.

The remaining 13 stars in the supplementary sample are all confirmed M dwarfs. The parallax measurements for both Vyssotsky 130 (a double star) and HD 218422 have substan-

tial uncertainties. For the present, we retain both stars in the sample, increasing the revised VC<sup>2</sup> sample to 558 main-sequence stars<sup>2</sup> in 448 systems. Relevant data for the additional stars are listed in Table 3. With the exception of LHS 1234 (Weis, 1996), prior observations are scarce, and most lack radial velocity data. For those stars, the space motions listed in Table 3 are computed for  $V_r = 0 \text{ km s}^{-1}$ .

## 2.2. Biases and completeness

A reliable determination of the properties of the local Galactic Disk demands an unbiased, representative stellar dataset. It is to that end that we constructed the VC<sup>2</sup> sample described in the previous section. However, while the  $\rho(d)$  and  $\frac{V}{V_{max}}(d)$  measurements show that the sample as a whole is broadly consistent with our requirements, subtle biases may remain, particularly since the stars are drawn primarily from a pre-existing catalogue (the pCNS3) rather than an unbiased all-sky survey. On the positive side, our VC<sup>2</sup> sample has the advantage that trigonometric parallax measurements are the dominant contributor to distance estimates for 90% of the systems. This is in contrast to the original PMSU1 VC sample, where 40% of the stars lacked accurate astrometry.

Two potential sources of bias are proximity to the Galactic Plane, where crowding might be a problem leading to omission of nearby stars; and proper motion-based selection, which could bias against nearby stars with low space motions. Considering the former issue, Figure 3 plots the distribution of the VC<sup>2</sup> sample on the celestial sphere. Based on the areal coverage, we expect 15.9% of the sample to lie within  $\pm 10^\circ$  of the Galactic Plane; in fact, 69 of the 448 systems ( $15.4 \pm 1.9\%$ ) lie within those limits. We conclude that crowding in the Galactic Plane is not a significant contributor to incompleteness in the VC<sup>2</sup> sample<sup>3</sup>

A greater concern is the potential for kinematic bias. As discussed in PMSU1 and PMSU2, most stars in the pCNS3 were identified based on their having high proper motion. Those stars are drawn predominantly from three major proper motion surveys: the Lowell survey, limited to  $\mu > 0.26'' \text{ yr}^{-1}$  (Giclas, Burnham & Thomas, 1971); the Luyten Half Second catalogue (LHS),  $\mu > 0.50'' \text{ yr}^{-1}$ , (Luyten 1979); and the New Luyten Two-Tenths Catalogue (NLTT),  $\mu > 0.18'' \text{ yr}^{-1}$ , (Luyten, 1980). Those limits correspond to transverse

---

<sup>2</sup>There are an additional four white dwarf and three brown dwarf companions.

<sup>3</sup>We note that there is a statistically significant bias against low-latitude systems if we consider low luminosity stars in the full pCNS3: of the 395 stars north of  $-30^\circ$  with  $M_V > 13$ , only 41, or  $10.4\% \pm 1.8\%$ , lie within  $10^\circ$  of the plane. The distance and  $M_V$  limits imposed in defining the VC<sup>2</sup> sample have eliminated this potential source of bias.

velocities of, respectively,  $24.6 \text{ km s}^{-1}$ ,  $47.4 \text{ km s}^{-1}$  and  $17.1 \text{ km s}^{-1}$  at 20 parsecs. Of the three surveys, the last has received least attention. While Weis (1986, 1987, 1988) has obtained (B)VRI photometry for many of the brighter ( $m_r \leq 13.5$ ) red stars in the NLTT, it is only recently that systematic attempts have been made to identify nearby stars amongst the fainter members of that catalogue (Reid & Cruz, 2001; Salim & Gould, 2002). Thus, there is a clear potential for bias against stars with low tangential motions in both the pCNS3 and the VC<sup>2</sup> sample.

We can test for kinematic bias by comparing the proper motions and transverse motions of the full VC<sup>2</sup> sample against similar data for the subset of stars which are included in the objective prism surveys (Vyssotsky, 1956; Upgren *et al.*, 1972). Since the latter stars were identified based on spectral type, that sample should be free of any kinematic selection effects. Two hundred and nine of the 448 systems in the VC<sup>2</sup> sample are in the Vyssotsky catalogue, while the Upgren *et al.* survey contributes four systems.

Most of the spectroscopically-selected stars are early-type M dwarfs, and those stars lie predominantly at larger distances in the VC<sup>2</sup> sample. This is illustrated in the upper panels of Figure 4. Since the average distance of the spectroscopic subset is higher than the full sample, we must compare the tangential velocity distributions, rather than the proper motion distributions. That comparison is shown in the lower panels of Figure 4, where the dotted line in the right-hand panel marks the fractional contribution of the spectroscopic subset to the full sample. If there were a significant bias against stars with low transverse motions, we would expect the proportion of spectroscopically-selected stars to rise with decreasing  $V_{tan}$ . The data show little evidence for that effect. Dividing the distribution into two subsets, with  $V_{tan} \leq 20 \text{ km s}^{-1}$  and  $V_{tan} > 20 \text{ km s}^{-1}$ , the ratios  $\frac{N_{prism}}{N_{tot}}$  are  $44.0 \pm 7.4\%$  and  $48.6 \pm 4.7\%$ , respectively.

Our tests therefore reveal no evidence for significant bias in the VC<sup>2</sup> sample either against stars lying within 10 degrees of the Galactic Plane, or against stars with low tangential motions. On that basis, we conclude that the VC<sup>2</sup> sample provides a reliable dataset for examining the space density and kinematics of the local Galactic Disk population.

### 3. The Luminosity Function

#### 3.1. The Luminosity Function

We next consider how the revised distances obtained by Hipparcos affect the nearby-star luminosity function,  $\Phi(M_V)$ . We also take this opportunity to redetermine  $\Phi(M_V)$  for earlier-type (BAFGK) main-sequence stars in the Solar Neighbourhood, and to identify lower-mass

companions to those stars which should be added to the PMSU M dwarf statistics. Despite the availability of Hipparcos data for more than half a decade, many recent luminosity-function analyses are still based on the statistics compiled by Wielen, Jahreiß & Krüger (1983) from the second Catalogue of Nearby Stars (Gliese, 1969; CNS2) and its supplement (Gliese & Jahreiß, 1979). An exception is the sample discussed by Kroupa, 2001. Clearly, the systematics evident in Figure 1 have a significant influence on our estimate of the local density of main-sequence stars.

The Hipparcos catalogue has a formal completeness limit of

$$V = 7.9 + 1.1\sin|b|$$

so the 25-parsec sample is effectively complete over the whole sky for  $M_V \leq 5.9$ . However, since the mission involved pointed observations of pre-selected targets, the survey includes a high proportion of stars known or suspected of being in the immediate Solar Neighbourhood. Indeed, Jahreiß and Wielen (1997) argue that the Hipparcos catalogue is essentially complete to  $M_V = 8.5$  for stars within 25 parsecs of the Sun, providing a useful complement to the  $8 < M_V < 16$  VC<sup>2</sup> sample.

We have identified 831 Hipparcos stars with  $\pi_H \geq 40$  milliarcseconds (mas) and  $M_V \leq 8.0$ . Three issues need to be addressed before deriving a luminosity function from this dataset: the evolutionary status of the individual stars; binarity and multiplicity; and the local intermix of stellar populations. The first and last considerations are illustrated in Figure 5, which plots the ( $M_V$ , (B-V)) colour-magnitude diagram for all 1477 stars in the Hipparcos catalogue with  $\pi_H \geq 40$  mas. Evolved stars clearly make a significant contribution at brighter magnitudes, and we have excluded them by eliminating stars which meet the following criteria,

$$M_V < 7.14(B - V) - 1.0, \text{ and } M_V < 5.0$$

This removes 41 stars from the sample.

Figure 5 includes a number of stars lying well below the disk main sequence. Most are fainter than  $M_V=8.0$  and are either white dwarfs, stars with substantial uncertainties in the measured parallax, or stars lacking (B-V) colours. Four stars, however, lie just below the main sequence with  $6 < M_V < 8$ . These are the halo subdwarfs HIP 18915 (HD 25329, [Fe/H]=-1.6), HIP 57939 (HD 103095, [Fe/H]=-1.4), HIP 67655 (HD 120559, [Fe/H]=-0.94) and HIP 79537 (HD 145417, [Fe/H]=-1.25). While the statistics are not overwhelming, a total of four subdwarfs in a sample of  $\sim 650$  FGK disk dwarfs implies a local number ratio of  $\sim 0.6 \pm 0.3\%$ , a factor of three higher than the density normalisation adopted for the halo in most Galactic structure analyses. All four stars are excluded from the present analysis.

Finally, we have checked SIMBAD for references to binary and multiple systems amongst

the remaining 786 stars. Thirteen systems have wide companions listed separately in the Hipparcos database, while a further 213 have unresolved companions at small separations or wide companions which are not included in the Hipparcos dataset. Where necessary, we have adjusted the photometry to allow for the contribution from fainter components, most notably in the case of HIP 66212 (HD 110836), which the uncorrected Hipparcos data place well above the main sequence. As illustrated in Figure 6, these corrections move a handful of primary stars to magnitudes fainter than  $M_V=8.0$ .

Even after applying photometric adjustments, a small number of stars still lie well above the main sequence in figure 6. Some (e.g. Gl 610) may be unrecognised binaries. Several, however, are primaries in binary systems (e.g. Gl 795A, GJ 1161A, Gl 118.2A), and the presence of the known secondary may affect either the photometry or the astrometry. Others are metal-rich stars (e.g. Gl 614, Gl 848.4 and HD 217107, all known to harbour extrasolar planets), while still others, lying near the base of the subgiant branch, may be slightly evolved (e.g. Gl 19, Gl 368). Further spectroscopy and photometry are required to resolve these issues completely.

We noted above that the Hipparcos dataset is expected to be effectively complete within 25 parsecs for stars with  $M_V < 8.5$ . We can test this hypothesis using the same techniques applied to the PMSU M dwarfs in §2. Figure 7 plots the run of density with distance for systems where the primary has  $M_V = 4.5 \pm 0.5, 5.5 \pm 0.5, 6.5 \pm 0.5$ , and  $7.5 \pm 0.5$ . The first point marks the average density within a sphere, radius 16 parsecs, centred on the Sun; subsequent point plot the densities within annuli of radii 16 to 18, 18 to 20, 20 to 22 and 22 to 25 parsecs. Given Poisson uncertainties, there is no evidence for a significant decline in completeness as one approaches the 25-parsec distance limit.

Our final sample includes 764 Hipparcos systems with  $d < 25$  parsecs and  $M_V < 8.0$ . A further twelve binaries have primaries with  $8 < M_V < 9$ . Four of those stars are already included in the PMSU sample, while three stars lie beyond 22 parsecs (the PMSU distance limit appropriate to this absolute magnitude). The remaining five stars are added to the PMSU sample. We also extend coverage to  $M_V \geq 16$  by adding data for the three systems currently known with  $d < 5$  parsecs and  $\delta > -30^\circ$  (GJ 1111, Gl 406 and LHS 292). Table 4 gives final statistics for the combined PMSU and Hipparcos 25-parsec samples, and Figure 8 plots the composite luminosity function,  $\Phi(M_V)$ .

We have compared our results against the luminosity function derived by Wielen, Jahreiß & Krüger (1983). The space densities derived here are systematically lower than in the earlier study, reflecting the systematic errors present in pre-Hipparcos distance estimates. Kroupa (2001) finds similar results in his analysis. Overall, we derive a local number density of 0.106 main sequence stars  $\text{pc}^{-3}$ , and a density of 0.0725 systems  $\text{pc}^{-3}$ . With evolved systems

contributing a further 41 systems within 25 parsecs ( $6.3 \times 10^{-4} \text{ pc}^{-3}$ ), the average separation between systems is  $\sim 2.4$  parsecs.

### 3.2. Binarity and Multiplicity

The 764 systems in our Hipparcos 25-parsec upper main-sequence sample include 538 single stars, 204 binaries (including 8 low amplitude spectroscopic binaries from Nidever *et al.*, 2002), 22 triples and 4 quadruple systems. The resultant multiplicity fraction is only  $30.1 \pm 2.4\%$ , somewhat lower than the value of 44% derived in the standard reference for this subject, Duquennoy & Mayor’s (1991, DM91) analysis of observations of solar-type dwarfs. This discrepancy may reflect poorer observational coverage of the Hipparcos sample. Even with the addition of the extensive radial velocity data from the Lick/Keck planet-search survey, summarised by Nidever *et al.* (2002), 98 stars lack radial velocity measurements, and we noted in the previous section that a number of stars lie above the main sequence, suggesting unrecognised binarity.

An alternative possibility is that the multiplicity fraction measured for the 25-parsec sample is more reliable than the DM91 statistics. The lower binarity might be a consequence of the larger magnitude range spanned by the present sample, since M dwarfs are known to have a lower fraction of stellar companions than solar-type stars (Fischer & Marcy, 1992; RG97). In addition, the improved parallax data lead to a better-defined sampling volume for the present dataset than for the DM91 dataset. We explore these issues here.

In analysing the multiplicity of solar-type stars, Duquennoy & Mayor’s intention was to define a volume-limited sample, including systems with spectral types between F7 and G9, declinations  $\delta > -15^\circ$  and parallaxes exceeding 45 milliarcseconds. However, since the parallaxes were drawn from the CNS2, they are subject to the systematic errors and potential biases illustrated in Figure 1. Fortunately, all of the DM91 stars are included in the Hipparcos catalogue.

Figure 9 compares parallax data listed in the CNS2 against Hipparcos measurements for the DM91 reference sample. As expected, over 40% of the sample lie beyond the nominal 25-parsec distance limit, including almost all stars with  $(B-V) > 0.8$ , most of which are subgiants. Only 102 systems have  $\pi_H \geq 45$  milliarcseconds. However, of those 102 systems, 42 are double or multiple, giving a multiplicity fraction of  $41 \pm 7\%$ , consistent with the value of 44% derived for the full dataset in DM91. Observational bias in the DM91 sample is therefore not likely to be responsible for the discrepancy with respect to the Hipparcos 25-parsec sample.

Even with the extensive temporal coverage and high accuracy provided by the CORAVEL

radial velocity observations, it is likely that a significant number of binary systems remain unrecognised amongst the DM91 G-dwarf sample. Binary systems with high inclination and/or long period have low velocity amplitudes, and are therefore more difficult to detect. Duquennoy & Mayor concluded that their analysis might underestimate the binary fraction amongst G dwarfs by approximately one-third, implying a true multiplicity close to 60%. On the other hand, 47 of the 60 “single” stars in the  $\pi_H \geq 45$  mas DM91 sub-sample are included in the Lick/Keck planet search program: 46 are classed as having stable radial velocities ( $\sigma_V < 0.1 \text{ kms}^{-1}$ ); only HIP 98819 (Gl 779) is identified as a confirmed spectroscopic binary (Nidever *et al.*, 2002).

Based on these results, we take 60% as a likely upper limit for the multiplicity of the upper main-sequence stars in the Hipparcos 25-parsec sample. Given the relatively sparse observational scrutiny, we assume that the known secondaries are characteristic of the sample as a whole, and therefore allow for potential “missing” binary companions by giving double weight to known binary components in the statistical analysis. Figure 10 shows the resultant effect on  $\Phi(M_V)$ : the space densities are still systematically lower than the Wielen *et al.* (1983) values. The overall space density becomes  $0.112 \text{ stars pc}^{-3}$ .

## 4. The Mass Function

### 4.1. The Mass-Luminosity Relation

The mass-luminosity relation is a key ingredient in transforming the stellar luminosity function to a mass function. Since we have only B, V data for most of the stars in the present sample, we require a relation between mass and  $M_V$ . In general, masses can be derived only for stars in binary systems (gravitational lensing offers the potential for deriving accurate masses for single stars, but requires particular source-lens geometries). Henry & McCarthy (1993) provided the first extensive analysis of lower main-sequence astrometric binaries. They derive a three-segment fit in the  $(M_V, \log(\text{mass}))$  plane, extending from  $2M_\odot$  to the hydrogen-burning limit. Together with their mass- $M_K$  and mass- $M_{bol}$  relations, this calibration has served as the primary reference over the last decade.

Most recent attention has centred on low-mass stars, with the addition of new data from high-precision HST (Henry *et al.*, 1999) and ground-based astrometry, and from high-accuracy radial velocity measurements (Delfosse *et al.*, 1999; Ségransan *et al.*, 2000). Delfosse *et al.* (2000: D00) have used these new observations to derive a revised mass- $M_V$  relation for lower main-sequence stars,

$$\log M = 10^{-3} \times [0.3 + 1.87M_V + 7.614M_V^2 - 1.698M_V^3 + 0.06096M_V^4]$$

As Figure 11 shows, this relation predicts higher masses by 10 to 15% than Henry *et al.*’s calibration for  $11 < M_V < 15$ .

Delfosse *et al.* limit their analysis to M dwarfs, and Henry *et al.*’s piecewise mass- $M_V$  relation extends only to  $2M_\odot$ , but the Hipparcos 25-parsec sample includes more massive A- and B-type stars. We have therefore used the data compiled by Andersen (1991) for eclipsing binary systems to derive an empirical mass- $M_V$  relation covering the upper main-sequence. That relation is

$$\log M = 0.477 - 0.135M_v + 1.228 \times 10^{-2}M_v^2 - 6.734 \times 10^{-4}M_v^3$$

and is plotted in Figure 11. We combine that relation with the D00 result, setting the boundary between the two calibration at  $M_V=10.0$ , where the agreement is better than 5%.

In addition to these empirical calibrations, Kroupa, Tout & Gilmore (1993, KTG) derived a semi-empirical mass- $M_V$  relation. Adopting the Wielen *et al.* (1983) luminosity function as a reference, they represent the mass function as a three-component power-law, and vary the indices to minimise residuals in the mass- $M_V$  relation. Figure 11 compares their derived relation against the empirical results. The KTG calibration, spanning absolute magnitudes between  $M_V=+2$  and  $+17$ , matches the D00 relation at low masses, and lies up to 8% below the empirical relation (i.e. predicts lower masses at a given  $M_V$ ) for solar-mass stars.

## 4.2. The Present-day Mass Function

We have computed present-day mass functions using both the D00 empirical calibration and the KTG semi-empirical relation, extending both to higher masses using our fit to the Andersen eclipsing binary dataset. Figure 12 shows the results derived from the empirical calibration. Defining

$$\xi(M) = \frac{dN}{d \log M} \text{ and } \psi(M) = \frac{dN}{dM}$$

the uppermost panel plots  $\xi(M)$  for the Hipparcos 25-parsec and the PMSU samples (i.e. the dataset used to construct  $\Phi(M_V)$  in Figure 8). The dotted histogram shows the mass function derived from single stars and primaries in multiple systems. The middle panel in Figure 12 plots  $\xi_{2B}(M)$ , where double weight is given to the Hipparcos 25-parsec secondary components (i.e. the dataset used to construct Figure 10). Adding the hypothetical as-yet-undiscovered binaries produces little change in the overall morphology. Integrating the mass functions, we derive a local mass density of  $\rho_{MS} = 0.0310 M_\odot pc^{-3}$  from  $\xi(M)$  and  $0.0338 M_\odot pc^{-3}$  when double weight is given to the secondaries in the Hipparcos sample. We note that white dwarfs contribute a further  $0.004 M_\odot pc^{-3}$  (RG97).

We have also used the empirical mass- $M_V$  relation to re-compute the mass function derived from the northern ( $\delta \geq -30^\circ$ ) 8-parsec sample. The original sample from RG97 has been updated to take into account Hipparcos parallax data and new stellar companions (Reid *et al.*, 1999; R99). Chabrier & Baraffe (2000) and Kroupa (2001) have suggested that this sample provides unreliable statistics, both through the inclusion of stars whose distances rest on photometric/spectroscopic parallax estimators, and through incompleteness. Neither objection is valid. As emphasised in R99, 100 of the 104 systems have accurate ( $\epsilon < 10\%$ ) trigonometric parallax measurements, while only a handful of addition have been identified since 1997. The most recent is 2MASS J1835379+325954, an M8 dwarf at 5.7 parsecs (Reid *et al.*, 2002a). As discussed in that paper, the  $>30\%$  deficit in number density between the 8-parsec and extrapolated 5-parsec sample (Henry *et al.*, 1997) includes a substantial contribution from bright ( $M_V < 14$ ) stars, and probably overestimates the shortfall by at least a factor of two.

The mass function derived from the 8-parsec sample is plotted in the lowermost panel of Figure 12. Again, the single star/primary mass function is plotted as a dotted histogram. Below  $1 M_\odot$ , the results are statistically identical to those based on the composite Hipparcos 25-pc./PMSU analysis (i.e., employing a 5-parsec limit at  $M_V > 15$ ). The total mass density derived by integrating  $\xi_8(M)$  is  $0.0288 M_\odot pc^{-3}$ , the lower value reflecting the relative scarcity of G dwarfs within 8 parsecs of the Sun<sup>4</sup>.

Following Salpeter (1955), it is convenient to represent the mass function as a power-law,

$$\xi(M) = M^{-\alpha+1} \text{ and } \psi(M) = M^{-\alpha},$$

where  $\alpha = 2.35$  is the Salpeter slope. The mass functions plotted in Figure 12 are all well represented by a two-component power-law. Both Hipparcos/PMSU analyses are consistent with  $\alpha = 1.35 \pm 0.2$  for  $0.1 < \frac{M}{M_\odot} < 1$  and  $\alpha = 5.2 \pm 0.4$  for  $M > 1M_\odot$ . The steep slope at masses above  $1M_\odot$  emphasises the fact that  $\xi(M)$  is the present-day mass function (Miller & Scalo, 1979); our calculations take no account of higher mass stars which have evolved off the main sequence over the lifetime of the Galactic disk. The 8-parsec sample has fewer high mass stars than the Hipparcos dataset, but still shows a clear break near  $1M_\odot$ , and we derive  $\alpha = 1.15 \pm 0.2$  for  $0.1 < \frac{M}{M_\odot} < 1$ , matching the original RG97 analysis. In each case, fitting to the single-star/primary dataset flattens the distribution below  $1M_\odot$ , giving  $\alpha \sim 1$ , since secondaries make a proportionately higher contribution at lower masses.

---

<sup>4</sup>We note that the  $2\sigma$  deficit of G dwarfs in a comparison of the 8-parsec and 25-parsec samples has the same statistical weight as the  $2\sigma$  excess of  $M_V=16$  stars in a comparison between the 5-parsec and 8-parsec samples. There appears to be little concern, however, over ‘missing’ G dwarfs within 8 parsecs of the Sun.

Figure 13 compares results from the empirical and semi-empirical mass- $M_V$  calibrations. The derived mass functions are in broad agreement, particularly at low masses. As might be expected from Figure 11, the main differences arise at near-solar masses. Rather than a single break at  $\sim 1M_\odot$ , the semi-empirical relation produces changes in slope at  $\sim 0.7M_\odot$  and  $\sim 1.1M_\odot$  (masses close to the break points chosen by KTG in their calibration procedure).

Fitting  $\xi_{KTG}(M)$  as a combination of power-laws, we find  $\alpha = 1.3 \pm 0.15$  for  $0.1 < \frac{M}{M_\odot} < 0.7$  (fitting  $0.15 < \frac{M}{M_\odot} < 0.7$  gives  $\alpha = 1.03 \pm 0.11$ ),  $\alpha = 2.8 \pm 0.4$  for  $0.7 < \frac{M}{M_\odot} < 1.1M_\odot$ , and  $\alpha = 4.8 \pm 0.15$  for  $M > 1.1M_\odot$ . Not unexpectedly, these results are very similar to those derived by Kroupa (2001). Integrating over the mass function, we find that main sequence stars contribute  $0.0300 M_\odot pc^{-3}$  to the local mass density. As with the empirical calibration, allowing for additional binaries amongst the Hipparcos 25-parsec sample increase  $\rho_{MS}$  by  $\sim 10\%$ .

Comparing  $\xi(M)$  and  $\xi_{KTG}(M)$ , the main difference is the steepening of the latter between  $\sim 0.7$  and  $1.0 M_\odot$ , reflecting the differences in the mass- $M_V$  relations evident in Figure 11. Additional calibrating binaries in this mass range would be clearly be very useful. That discrepancy apart, there is considerable similarity between the global properties of the two present-day mass functions plotted in Figure 13:  $\alpha \sim 1.2$  at low masses;  $\alpha \sim 5$  at super-solar masses; and, depending on the binary fraction, an integrated mass density of  $0.030$  to  $0.034 M_\odot pc^{-3}$ .

### 4.3. The Initial Mass Function

The mass function,  $\xi(M)/\psi(M)$ , specifies the relative number of main sequence stars as a function of mass in the local Galactic disk at the present time. A more fundamental quantity is the initial mass function, denoted here as  $\Xi(M)$  (logarithmic mass units) or  $\Psi(M)$ , the relative number of stars forming as a function of mass. Three factors need to be taken into account in converting the present-day mass function to the initial mass function: stellar evolution; the density distribution perpendicular to the Plane; and the local mix of stellar populations.

Salpeter (1955) originally pointed out the necessity of allowing for evolution beyond the main sequence in computations of the ‘original mass function’. M dwarfs have main sequence lifetimes,  $\tau_{MS}$ , well in excess of 20 Gyrs, so  $\xi(M)$  includes low-mass stars spanning the full history of star formation in the Disk. Higher mass stars have shorter hydrogen-burning lifetimes, and  $\xi(M)$  only takes account of stars with ages,  $\tau < \tau_{MS}$ . Thus, the present-day census includes only a fraction of the total population if  $\tau_{MS}$  is less than the age

of the Galactic disk,  $\tau_{disk}$ . Correcting the observed numbers for this effect requires that we estimate the age of the disk and adopt a stellar birthrate as a function of time.

Binney, Dehnen & Bertelli (2000) summarise the various techniques which have been used to estimate the age of the local disk population. Those include analyses of the low-luminosity cutoff in the disk white dwarf luminosity function, measurements of isotopic ratios, isochrone matching for individual stars and quantitative analysis of the distribution of stars in the HR diagram. Individual age estimates range from 7 to 15 Gyrs; we adopt  $\tau_{disk} = 10$  Gyrs in the present calculations. Following the discussion in PMSU3, we assume a constant star formation rate, so the correction factor is given by

$$f_{MS} = \frac{\tau_{Disk}}{\tau_{ms}}, \text{ for } \tau_{MS} < \tau_{Disk}$$

These corrections are applied on a star-by-star basis to the Hipparcos sample, with the appropriate main-sequence lifetimes computed from

$$\log \tau_{MS} = 1.015 - 3.491 \log M + 0.8157(\log M)^2$$

This relation is derived from the solar abundance models computed by Schaller *et al.* (1992).

The decrease in main-sequence lifetime with increasing mass also requires accounting for the vertical density distribution,  $\rho(z)$ . Velocity dispersion increases with age, so the younger average age of higher-mass stars leads to lower velocities and a density distribution which is confined more closely to the Plane. Thus, a local volume-limited sample of the latter stars, drawn from near the galactic mid-Plane, includes a larger fraction of the total population.

We correct for this effect following Miller & Scalo. The vertical density distribution of disk stars can be represented by an exponential distribution, scaleheight  $z_0$ . Most recent studies derive a value of  $z_0 \sim 250$  parsecs for long-lived main-sequence stars ( $M_V > 4$ ); younger upper main-sequence stars,  $M_V < 3$ , have lower velocity dispersions and a steeper density distribution,  $z_0 \sim 100$  parsecs (Haywood *et al.*, 1997; Siegel *et al.*, 2002). We adopt a scaleheight of 170 parsecs for stars with intermediate absolute magnitudes,  $3 < M_V < 4$ . Deriving accurate estimates of surface density from  $\psi(M)$  is a complex operation, requiring modelling of the overall potential (see, for example, Kuijken & Gilmore, 1989). We assume that the effective surface densities,  $\Sigma$ , scale linearly with  $z_0$ , i.e.

$$\Sigma \propto \rho_0 z_0$$

where  $\rho_0$  are the volume densities plotted in Figures 12 and 13.

Finally, since we aim to derive  $\Xi(M)$  for the disk, we need to take account of Solar Neighbourhood stars which are members of other stellar populations. For present purposes,

we consider three components: disk, thick disk and halo (stellar, not dark matter). While last component makes a negligible contribution locally (§3.1), approximately 10% of the stars in the immediate Solar Neighbourhood are part of the more extended thick disk (see §5.2). The full characteristics of the latter population, particularly the abundance and age distribution, remain uncertain, but starcounts at  $z > 1000$  pc. demonstrate there are few, if any, stars younger than a few Gyrs, and that the vertical density distribution has a scaleheight three to four times that of  $M_V > 4$  disk stars (Siegel *et al.*, 2002). Given those results, we assume that 90% of local stars with  $M_V \geq 4$  are disk dwarfs, and scale  $\psi(M)$  accordingly.

Figure 14 shows the initial mass functions derived from  $\xi(M)$  and  $\xi_{KTG}(M)$ ; both datasets are based on the observed Hipparcos 25-parsec and PMSU samples (i.e., we have not applied corrections for potential undetected secondary components). In both cases,  $\Xi(M)$  can be represented as a two-component power-law: with the empirical mass- $M_V$  relation, the data are consistent with  $\alpha = 1.3 \pm 0.2$  at  $M < 1.1M_\odot$ , and  $\alpha = 2.8 \pm 0.25$  at higher masses; adopting the semi-empirical mass- $M_V$  relation gives  $\alpha = 1.1 \pm 0.15$  at  $M < 0.6M_\odot$ , and  $\alpha = 2.5 \pm 0.15$  at higher masses, consistent with results derived by Kroupa (2001). Reducing the assumed age of the Disk to 8 Gyrs steepens  $\alpha$  at high masses by  $\sim 0.15$ ; increasing  $\tau_{disk}$  to 12 Gyrs flattens  $\alpha$  to a similar extent.

#### 4.4. Modelling $\Xi(M)$ : power-laws or log-normal functions?

Power laws provide a mathematically simple means of representing the stellar initial mass function, and give an adequate match to the data plotted in figure 14. Some recent studies, however, find that mass functions of this form are less successful in matching data for young clusters and associations. In particular, Hillenbrand & Carpenter (2000) find that  $\psi(M)$  peaks at  $\sim 0.15M_\odot$  in the central regions of the Orion Nebula Cluster<sup>5</sup>. Miller & Scalo (1979) provided an alternative to power laws in their log-normal representation of the initial mass function,

$$\Xi(M) = C_0 \exp(-C_1(\log M - C_2)^2)$$

where  $C_0, C_1$  and  $C_2$  are constants, defining the normalisation, width and maximum of the initial mass function.

The main impact of adopting a log-normal representation of  $\Xi(M)$  is twofold: first, the existence of a preferred mass ( $10^{C_2}$ ) has implications for star formation models; second,

---

<sup>5</sup>We note that Luhman *et al.* (2000), using a different set of evolutionary tracks, find that the ONC mass function is consistent with a power-law,  $\alpha \sim 1$ , to  $\sim 0.04M_\odot$ .

the extrapolation below the hydrogen-burning limit affects expectations of the frequency of brown dwarfs. Neither of the IMFs plotted in Figure 14 extends to substellar masses. Measuring  $\Psi(M)$  at those masses in the field is complicated severely by the rapid luminosity evolution of brown dwarfs, as discussed by R99. Modelling the mass function as a power law, R99 found that a simple extension of the low-mass star IMF ( $\alpha = 1.3 \pm 0.3$ ) provides a reasonable match to the (still scarce) observations. Chabrier (2002) arrives at similar conclusions. However, the field brown dwarf sample is likely to be dominated by longer-lived, higher-mass objects,  $M > 0.04M_{\odot}$ . As figure 14 shows, within those limits (0.04 to  $0.08M_{\odot}$ ), there is relatively little difference in slope between the Miller-Scalo functions and an  $\alpha \sim 1$  power law. More extensive observations of young clusters, and improved models for pre-main sequence dwarfs, still offer the best prospects of establishing  $\Psi(M)$  at these low masses.

We have matched log-normal distributions against the observations. We have fixed  $C_2 = -0.9$  and defined a goodness of fit statistic,

$$\chi_{\nu}^2 = \Sigma(\frac{(O - C)^2}{\epsilon^2})/\nu$$

where O, C are the observed and predicted values of  $\Xi(M)$ ,  $\epsilon$  is the associated Poisson uncertainty, and  $\nu = n_{bin} - 2$ . We allow both  $C_0$  and  $C_1$  to vary. The best-fit results are  $C_1=1.0$  for  $\Xi(M)$  and  $C_1=1.2$  for  $\Xi_{KTG}(M)$  (the values of  $C_0$  have no physical significance, since our density scaling has an arbitrary zeropoint). These results are plotted in figure 14, together with the best-fit match for  $C_1=1.15$ , the original value derived by Miller & Scalo (1979). The  $\chi_{\nu}^2$  values for those fits are 8.34 and 6.08, respectively (for  $\nu = n_{bin} - 3$ ) ; in comparison, the power-law representation gives  $\chi_{\nu}^2 = 4.34$  and 4.66, respectively.

In summary, log-normal Miller-Scalo functions provide a poorer representation of the overall shape of the derived IMFs than simple power-law fits. Having noted that, one should bear in mind the caveat that the differences between the two ‘observed’ functions plotted in Figure 14 highlight the continued potential for systematic effects introduced by changes in the mass-luminosity relation. Nonetheless, the main challenge facing star formation theory appears to lie in providing an explanation for the change in power-law index between 0.7 and 1.1  $M_{\odot}$ .

## 5. Galactic Disk Kinematics

In PMSU1 we used our observations of the VC sample to study the motions of local stars, and in PMSU2 we examined the different kinematics exhibited by M dwarfs with and without detectable H $\alpha$  emission. Those analyses were based on radial velocities derived from

the intermediate resolution spectra used to measure bandstrengths and determine spectral types. We can re-examine those issues using the more accurate distances and radial velocities measured for the VC<sup>2</sup> sample.

### 5.1. Solar Motion and the Schwarzschild velocity ellipsoids

We have used standard techniques (Murray, 1983) to parameterise the kinematics of the M dwarfs in the VC<sup>2</sup> sample. We calculate the Solar Motion and Schwarzschild ellipsoid parameters for (U, V, W) Galactic co-ordinates, where U is positive towards the Galactic Centre, V positive in the direction of rotation, and W positive towards the North Galactic Pole. This matches the co-ordinate system used in the pCNS3.

This standard calculation measures the velocity distributions of stars within a small spherical volume, centred on the Sun and lying near the midpoint of the Galactic Plane. Wielen (1974, 1977) has argued that weighting the velocity dispersion by the W velocity (effectively, the inverse residence time in the Plane) provides a more useful estimator. Those dispersions are calculated as follows:

$$\begin{aligned}\sigma_U^2 &= \sum_i (|W_i| U_i^2) / \sum_i |W_i| \\ \sigma_V^2 &= \sum_i (|W_i| V_i^2) / \sum_i |W_i| \\ \sigma_W^2 &= \frac{1}{2} \sum_i (|W_i| W_i^2) / \sum_i |W_i|\end{aligned}$$

Both sets of velocity dispersions are listed in Table 5, together with the mean velocity relative to the Sun, the Solar Motion. The results are consistent both with our previous studies, based on lower-accuracy radial velocities, and with other analyses of nearby star samples (e.g. Dehnen & Binney, 1998).

As in PMSU2, we have segregated M dwarfs in the VC<sup>2</sup> sample with measureable H $\alpha$  emission. In the PMSU2 analysis, the low-resolution spectroscopy limited this sample to stars with equivalent widths exceeding 1.0Å; in the present sample, with the higher-resolution PMSU3 echelle data, the effective limit is 0.1Å. Eighty-three stars in the VC<sup>2</sup> sample meet this criterion, and the resulting mean kinematics are listed in Table 5. As discussed in PMSU2, H $\alpha$  emission declined with increasing age, so it is no surprise that the unweighted velocity dispersions are significantly lower than those of the full VC<sup>2</sup> sample. In contrast, the weighted velocity dispersions are markedly higher. This reflects the influence of a small number of stars with large W velocities (e.g. GJ 1054, W=−95.3 km s<sup>−1</sup> and Gl 630.1, or CM

Dra,  $W = -83 \text{ km s}^{-1}$ ), and illustrates the vulnerability of this calculation to small number statistics.

We have also determined the mean kinematics for stars in the Hipparcos 25-parsec sample. As noted above, 98 of the 764 systems in this sample lack radial velocities, and those stars are not included in our statistics. Most of the latter systems have low proper motions, as one might expect given their pre-Hipparcos obscurity - seventy-four ( $\sim 75\%$ ) have  $\mu < 0.3'' \text{ yr}^{-1}$  and 73 have  $V_{tan} < 30 \text{ km s}^{-1}$ . Ignoring those stars in the present analysis may affect the derived (U, V, W) distributions at low velocities, although the comparisons in the following section suggest that this is not a severe effect.

We have divided the Hipparcos dataset into two sub-samples: 138 systems with  $M_V < 4$  (137 with  $V_r$  measurements); and 626 systems  $M_V \geq 4$  (528 with radial velocities). Table 5 lists the mean kinematics those datasets, and Figure 15 compares the (V, U) and (W, U) velocity distributions against data for the VC<sup>2</sup> sample. The fainter Hipparcos stars are kinematically indistinguishable from the M dwarf sample, as one would expect, given that both datasets should sample the same underlying population - disk dwarfs with ages spanning the star formation history of the Galactic disk. The brighter Hipparcos stars have significantly lower velocity dispersions than even the dMe sample, reflecting the short main-sequence lifetimes and younger ages of these more luminous stars. The derived kinematics for those stars are consistent with recent studies.

## 5.2. The M-dwarf velocity distribution and the thick disk

The r.m.s. velocity dispersions derived in the previous section provide a simple one-parameter characterisation of the velocity distribution in each component. While useful as a simple means of comparing different stellar samples, that parameterisation can be misleading if the underlying velocity distribution is non-Gaussian in nature. Probability plots (Lutz & Uppgren, 1980) provide a method of examining the velocity distributions in more detail: if a given sample is drawn from a Gaussian distribution, plotting the cumulative distribution in units of the measured r.m.s. dispersion gives a straight line.

Figure 16 shows (U, V, W) probability plots for the full VC<sup>2</sup> sample, the dMe stars from that sample, and both subsets of the Hipparcos dataset ( $M_V > 4/M_V < 4$ ). The full VC<sup>2</sup> dataset and the fainter Hipparcos sample have very similar velocity distributions, suggesting that even though the latter sample is not complete, the subset of stars with measured radial velocities is unbiased. The brighter Hipparcos stars and the dMe dwarfs, samples dominated by younger stars, have velocity distributions closest to those expected for

Gaussian dispersions, although both, particularly the emission-line stars, become non-linear at extreme velocities. A number of the higher-velocity dMe dwarfs are known to be close binaries (e.g. CM Dra). These stars could be older systems, where tidal locking maintains enhanced rotational velocities and stronger H $\alpha$  emission.

All four datasets exhibit near-linear distributions at low velocities, suggesting that each includes a core subset of stars with Gaussian velocity distributions. We have measured the slope of the central regions for each distribution. In U and W, the gradients are derived for the range  $-1 < \sigma < 1$ ; the V distributions become non-linear more rapidly at negative velocities (lagging the Solar rotational velocity), and we fit the slope in the range  $-0.5 < \sigma < 2$ . The resulting measurements are listed in Table 5.

We propose that the linear core in these probability distributions represents the disk population in each sample. The two younger datasets, the brighter Hipparcos stars and the dMe dwarfs, have been subjected to less secular scattering, and therefore have lower velocity dispersions. The non-linearities are more pronounced at large  $|\sigma|$  in the other two samples and, in at least U and W, are symmetric, suggesting the presence of a second, higher velocity dispersion component. The obvious candidate for the latter is the thick disk. Identified originally by Gilmore & Reid (1983), the thick disk is evident as a flattening of the density law,  $\rho(z)$ , at  $\sim 1 - 1.5$  kpc. above the Plane. Initial analyses of  $\rho(z)$  suggested a low local density normalisation ( $\rho_{TD}(z = 0) \sim 0.02\rho_{disk}(z = 0)$ ) and high scaleheight ( $>1.3$  kpc), but more recent studies (Haywood et al, 1997; Siegel et al, 2002) favour a higher normalisation ( $\sim 5\%$ ) and a smaller scaleheight (0.7 to 1 kpc.). Its origin remains uncertain, but, as noted in the previous section, the scarcity of main-sequence A and F stars indicates  $\tau > 3$  Gyrs. There are no direct, unbiased measurements of the abundance distribution.

The rotational properties of the thick disk are not yet well established, complicating analysis of the V-velocity distributions. However, we do not expect a significant Solar Motion in either U or W, while a stellar component with a larger scaleheight must also have a higher  $\sigma_W$  than disk dwarfs. Modelling the latter velocity distributions should therefore provide insight into both thick disk kinematics and the local density normalisation.

We have matched the observed W-velocity probability distributions of the VC<sup>2</sup> and faint Hipparcos samples against models derived by combining two Gaussian components ( $\sigma_1, \sigma_2$ ), with a relative normalisation,  $f = \frac{N_1}{N_2}$ . We set  $\sigma_1 = 16 \text{ km s}^{-1}$ , matching the core of the observed distribution, and define the mean velocity as  $W = -8 \text{ km s}^{-1}$  (VC<sup>2</sup>) and  $-6 \text{ km s}^{-1}$  (Hipparcos). We let  $\sigma_2$  vary from  $18 \text{ km s}^{-1}$  to  $60 \text{ km s}^{-1}$  in steps of  $2 \text{ km s}^{-1}$ , varying  $f$  between 0.02 and 0.20 at each velocity. At each step, we compute the rms residuals

$$R_s = \Sigma(W_i - W_c)^2$$

where  $W_i$  is the observed velocity and  $W_C$  the predicted velocity for the measured  $\sigma_i$  (the abscissa in the probability plots).  $R_s$  is computed for the range  $-2.5 < \sigma_i < 2.5$  to minimise the effect of outliers in the observed velocity distribution.

Matched against the models, both datasets exhibit a broad minimum in  $R_s$  centred at  $\sigma_2 \sim 36 \text{ km s}^{-1}$ ,  $f \sim 0.12$ . There is reasonable agreement between the model and the data for  $34 < \sigma_2 < 48 \text{ km s}^{-1}$  and  $0.1 < f < 0.2$  for the VC<sup>2</sup> sample, and for  $34 < \sigma_2 < 42 \text{ km s}^{-1}$  and  $0.1 < f < 0.16$  for the Hipparcos dataset. In general,  $\sigma_2$  and  $f$  are anti-correlated in those solutions. Figure 17 illustrates several examples. None of the models provide a good match to the data at  $|\sigma| > 2.5$ , where small number statistics can affect the observed distribution.

Analysing the U-velocity distribution gives similar results. Setting  $\sigma_1 = 34 \text{ km s}^{-1}$ , and matching the distribution for  $|\sigma| < 2.5$ , the best-fit values are  $\sigma_2 = 60$  to  $64 \text{ km s}^{-1}$ ,  $f = 0.1$  to  $0.12$  for the VC<sup>2</sup> sample, and  $\sigma_2 = 64$  to  $70 \text{ km s}^{-1}$ ,  $f = 0.1$  to  $0.14$  for the Hipparcos dataset. Both datasets are consistent with approximately 10% of Solar Neighbourhood stars being members of the higher-velocity component.

Summarising these results, a two-component Gaussian distribution with velocity dispersions ( $\sigma_1 = 16 \text{ km s}^{-1}$ ,  $\sigma_2 \sim 36 \text{ km s}^{-1}$ ,  $f = 0.12$ ) provides a good representation of the observed W-velocity distribution of Solar neighbourhood disk dwarfs. A two-component Gaussian with ( $\sigma_1 = 34 \text{ km s}^{-1}$ ,  $\sigma_2 \sim 62 \text{ km s}^{-1}$ ,  $f = 0.12$ ) matches the observations in U. In both U and W, approximately 10% of the sample resides in the higher velocity-dispersion component. Given the results from recent starcount analyses, it seems reasonable to identify the latter stars as the local constituents of the thick disk.

### 5.3. Ultracool M dwarfs and the thick disk

Reid *et al.* (2002b) have recently presented high-resolution echelle observations of a photometrically selected sample of ultracool M dwarfs (spectral types later than M7). One of the surprising results from that study concerns the velocity distributions, which have more similarity to our analysis of dMe dwarfs than the kinematics of the full VC<sup>2</sup> sample. This is unexpected, since almost all ultracool M dwarfs are expected to be hydrogen-burning stars, albeit with masses very close to the hydrogen-burning limit. With main-sequence lifetimes exceeding  $10^{12}$  years, ultracool dwarfs, like earlier-type M dwarfs, should span the full age range of the Galactic Disk. One would expect such stars to have experienced a similar history of dynamical interactions, leading to kinematics matching the full VC<sup>2</sup> sample, rather than the younger emission-line dwarfs.

A possible resolution to this dilemma lies with the two component model. The observed velocity dispersions of the ultracool dwarfs are

$$(\sigma_U, \sigma_V, \sigma_W) = (32, 17, 17)$$

These values are close to the velocity dispersions that we measure for the core of both the VC<sup>2</sup> and faint Hipparcos samples (Table 5). We have identified those core velocity dispersions as characteristic of the Galactic disk. Are the ultracool dwarfs essentially a pure disk sample?

There are two possible explanations for the absence of thick disk dwarfs in the ultracool sample. First, the result may be due to small number statistics: there are only 37 dwarfs in the photometrically-selected sample analysed by Reid *et al.*, implying an expected number of  $4 \pm 2$  thick disk dwarfs. Alternatively, a systematic difference in metallicity could lead to thick disk stars being intrinsically rarer amongst low-temperature, late-type dwarfs.

Expanding on the latter possibility, the location of the hydrogen-burning limit in the HR diagram is known to be a function of metallicity. This is illustrated most dramatically for extreme halo subdwarfs (e.g. NGC 6397, Bedin *et al.*, 2001), where the main-sequence terminates at  $M_V \sim 15$ ,  $(V-I) \sim 3$ , brighter and bluer than for the Galactic disk population. While the metal hydride absorption bands in those stars are consistent with late-type M dwarfs, the TiO absorption is closer to that observed in M3 dwarfs (Gizis, 1997). This behaviour is relevant because there are suggestions that the thick disk, as an old population, may have a mean metallicity  $\langle [Fe/H] \rangle < -0.4\text{dex}$ . This might be sufficient to move the hydrogen-burning limit to an effective spectral type of  $\sim M7$ , significantly reducing the contribution of thick disk dwarfs to an ultracool sample, without necessarily requiring a significant change in the underlying mass function.

We can test this hypothesis to a limited extent using data for the VC<sup>2</sup> sample. All of these stars have low-resolution spectroscopic observations, obtained as part of the PMSU survey. CaH and TiO band indices derived from those data can be used to provide a crude assessment of the metallicity distribution. Figure 18 plots bandstrengths for the M dwarfs in the VC<sup>2</sup> sample and for nearby intermediate (sdM,  $[Fe/H] \sim -1$ ) and extreme (esdM,  $[Fe/H] < -1.5$ ) subdwarfs from Gizis (1997). We fit mean relations to the VC<sup>2</sup> stars

$$\langle CaH2 \rangle = 0.128 + 0.714TiO5 - 0.205TiO5^2 + 0.266TiO5^3$$

and the intermediate subdwarfs,

$$CaH2_{sdM} = -0.219 + 2.632TiO5 - 4.149TiO5^2 + 2.656TiO5^3$$

The middle panel plots the raw residuals,

$$\delta CaH2 = CaH2_{obs} - \langle CaH2 \rangle$$

as a function of  $W$  velocity; the lowermost panel plots the normalised residuals,

$$\delta CaH2_N = (CaH2_{obs} - \langle CaH2 \rangle) / (CaH2_{sdM} - \langle CaH2 \rangle)$$

If thick disk dwarfs have systematically lower metallicities than disk dwarfs, one might expect a systematic trend in the residuals with increasing velocity. There is no evidence for such behaviour in these data. However, the uncertainties in the abundance calibration are obviously substantial, and could well obscure systematics at the expected level of  $\sim 0.4$  dex. A similar analysis of a volume-complete sample of G dwarfs, where abundances can be derived to higher accuracy, would be instructive.

## 6. Conclusions

In the first paper of this series (PMSU1), we used spectroscopic observations of stars in the pCNS3 to define a volume-limited sample of M dwarfs with absolute magnitudes in the range  $8 < M_V < 14$ , the VC sample. In the present paper, we have examined the effects of using Hipparcos distance estimates and adding newly-discovered M dwarfs which meet the relevant distance limits. The revised sample, the VC<sup>2</sup> sample, includes 548 main-sequence stars in 448 systems, and shows no evidence for systematic bias against stars with low space motions.

Using the revised sample, we have recomputed the stellar luminosity function,  $\Phi(M_V)$ . We have combined those measurements with Hipparcos data for brighter stars within 25 parsecs of the Sun to derive the luminosity function for main sequence stars with  $-1 < M_V < 17$ , making explicit allowance for potential unseen binary companions. The results are in good agreement with Kroupa’s (2001) analysis for  $M_V < 10$ , but we derive lower space densities for mid- and late-type M dwarfs.

We have transformed the observed luminosity function to a mass function using both empirical and semi-empirical mass- $M_V$  calibrations, with the latter taken from Kroupa, Tout & Gilmore (1993). The resulting present-day mass functions are in broad agreement, consistent with power-law distributions with  $\alpha \sim 1.2$  at low masses ( $M < 0.6M_\odot$ ) and  $\alpha \sim 5$  at high masses ( $M > 1.1M_\odot$ ). The semi-empirical mass- $M_V$  relation leads to a steepening in  $\psi(M)$  ( $\alpha \sim 2.2$  for  $0.6 < \frac{M}{M_\odot} < 1.1$ ). Data for additional binary stars with masses in the range  $0.8 < \frac{M}{M_\odot} < 1.2$  would be useful in resolving this discrepancy. However, there is little impact on the the mass density derived by integrating  $\psi(M)$ ; both analyses indicate that main-sequence stars contribute 0.030 to 0.033  $M_\odot pc^{-3}$  to the total mass density in the Solar Neighbourhood.

We have converted the observed present-day mass function to estimates of the initial

mass function by allowing for stellar evolution effects at high masses, and by integrating the density distribution perpendicular to the Plane. We also apply a 10% correction to allow for the presence of thick disk dwarfs in the local sample. The derived IMFs have a near-Salpeter slope at high masses,  $\alpha \sim 2.5 - 2.8$ , but are relatively flat at low masses,  $\alpha \sim 1.1 - 1.3$ .

We also consider the kinematics of Solar Neighbourhood stars. Analysis shows that both the M dwarfs in the VC<sup>2</sup> sample and the fainter stars ( $4 < M_V < 8$ ) in the Hipparcos 25-parsec dataset have similar velocity distributions. This is not unexpected, since both should include representatives from the full star formation history of the Galactic Disk. Both the brighter Hipparcos stars and the dMe dwarfs amongst the VC<sup>2</sup> sample have cooler kinematics, as expected for datasets with younger average ages. Detailed analysis of the U- and W-velocity distributions for the two older samples shows that both are well represented by two-component Gaussians, with approximately 10% of the stars in the higher-velocity component. We identify the latter as the local component of the thick disk. A comparable analysis of a well-defined sample of solar-type stars offers the potential for obtaining insight into the detailed properties of this Galactic component.

Finally, we suggest that the thick disk component may provide an explanation for the surprisingly low velocity dispersions measured for a photometrically-selected sample of ultracool dwarfs: if the thick disk is slightly metal-poor, the hydrogen-burning limit could lie close to the M7 boundary of the ultracool sample. As a result, the coolest M dwarfs may represent a pure disk sample, a conclusion supported by the agreement between their kinematics and the core velocity dispersions measured for the FGK and early/mid-type M dwarfs in our analysis.

This research was supported partially by a grant under the NASA/NSF NStars initiative, administered by the Jet Propulsion Laboratory, Pasadena. We have made extensive use of the Simbad database, maintained by Strasbourg Observatory, and of the ADS bibliographic service.

Table 2—Continued

NN	Name	distance pc.	Ref.	$M_V$	$V_r$ $\text{kms}^{-1}$	$\mu_\alpha$ '' $\text{yr}^{-1}$	$\mu_\delta$ '' $\text{yr}^{-1}$	U $\text{kms}^{-1}$	V $\text{kms}^{-1}$	W $\text{kms}^{-1}$	H $\alpha$ Å	Comments
3782	Gl 912	17.2 $\pm$ 3.4	1	9.96	17.1	-0.460	-0.354	46.8	0.8	-18.4	-0.37	
3786	GJ 1292	13.1 $\pm$ 0.4	2	11.13	-32.4	1.032	-1.032	-21.0	-84.1	-41.8	-0.24	85/15
3791	Gl 913	17.4 $\pm$ 0.7	1	8.43	7.6	0.642	-0.003	-49.2	-17.0	-12.4	-0.50	

Note. — Column 1 lists the identifier from the PMSU1 tables; Column 2 gives the pCNS3 name;  
Column 3 lists the distance estimate and associated uncertainty - an uncertainty of  $\pm 0.0 \text{ km s}^{-1}$  indicates  $\epsilon_d < 0.1$  parsecs;  
Column 4 gives the source of the distance estimate:  
1 - trigonometric parallax from the Hipparcos catalogue (ESA, 1997)  
2 - PMSU1 (Reid *et al.*, 1995). The relative weights given to trigonometric and spectroscopic parallax measurements are listed in column 13: for example, 85/15 indicates that 85% of the weight rests with  $\pi_{trig}$ .  
3 - trigonometric parallax from pCNS3 (Jahreiss & Gliese, 1991)  
Column 5 lists the visual absolute magnitude; Column 6 lists the radial velocity, usually from either PMSU3 or Delfosse *et al.* (1998), but see notes to column 13. The echelle data are accurate to  $\pm 1 \text{ km s}^{-1}$ ; the low-resolution data are accurate to  $\pm 10 \text{ km s}^{-1}$   
Columns 7 and 8 give the proper motion in arcseconds/year from either Hipparcos data (column 4 = 1) or the pCNS3;  
Columns 9, 10 and 11 give the derived (U, V, W) space motions;  
Column 12 lists the H $\alpha$  equivalent width, where, following PMSU3, a negative value indicates absorption;  
Column 13 lists comments on individual stars:  
the relative weights of the trigonometric/spectroscopic parallax measurements contributing to  $d$  are given (see above);  
‘low-res’ indicates that the star has no PMSU3 echelle observations, and both the H $\alpha$  equivalent width and the radial velocity are from the PMSU1 low-resolution data.

Table 3. Basic data for supplementary stars

17.5				2	6	1		50.93	76.39

Note. — Column 2 lists the number-magnitude distribution of single stars and primary stars in the Hipparcos 25-parsec sample; column 3 gives the magnitude distribution for all known companions; column 4 lists the number of companions which fall within the distance limits given in Table 1. Columns 5, 6 and 7 provide the same statistics for the PMSU4 sample, and column 8 gives the contribution from the supplementary stars listed in Table 3. Combining the samples, the luminosity function due to primaries and single stars is listed in column 9, while the space densities given in column 10 include the contribution from the companions listed in columns 4 and 7.

Table 5. Kinematics of nearby Stars

Sample		$\langle U \rangle$ kms <sup>-1</sup>	$\langle V \rangle$ kms <sup>-1</sup>	$\langle W \rangle$ kms <sup>-1</sup>	$\sigma_U$ kms <sup>-1</sup>	$\sigma_V$ kms <sup>-1</sup>	$\sigma_W$ kms <sup>-1</sup>	Comment
VC <sup>2</sup> dM+dMe	436	-9.7	-22.4	-8.9	37.9	26.1	20.5	unweighted
					42.1	32.9	32.2	W  weighted
					34	18	16	core
VC <sup>2</sup> dMe	83	-15.4	-16.5	-10.1	25.0	21.1	17.8	unweighted
					33.6	44.6	36.1	W  weighted
					12	11	11	core
Hipparcos $M_V < 4$	137	-7.8	-10.0	-8.9	27.4	14.2	14.2	unweighted
					29.4	15.4	21.8	W  weighted
					35	18	16	core
Hipparcos $M_V \geq 4$	532	-12.7	-22.8	-6.5	39.9	27.9	19.1	unweighted
					45.2	33.4	29.2	W  weighted
					26	14	10	core

Note. — Unweighted:  $\sigma = \Sigma((x_i - \bar{x})/n)$   
|W| Weighted: weighted using Wielen’s prescription (see text)  
core: linear fit to central regions of probability distributions (Figure 16).

### Figure Captions

Fig. 1.— A comparison between distance determinations pre- and post-Hipparcos. The upper panel plots the difference,  $\Delta d = d_{PMSU4} - d_{PMSU1}$ , for the 1684 M dwarfs. The lower panel shows the effect on the original VC sample, plotting the revised distances and absolute magnitudes in comparison to the PMSU1 distance limits. 71 of 499 systems fall outwith the formal sampling volume.

Fig. 2.— The run of density with increasing distance for pCNS3 M dwarfs as a function of absolute magnitude. The dotted vertical lines mark the distance limits for the volume-complete sample; the dashed vertical line for  $M_V=9.5$  marks the value adopted in Paper I.

Fig. 3.— The distribution of the VC<sup>2</sup> systems on the celestial sphere, as a function of both equatorial and Galactic co-ordinates. The solid line indicates the  $-30^\circ$  limit in both cases.

Fig. 4.— Comparison between the properties of the full VC<sup>2</sup> sample and the subset of stars identified in the Vyssotsky and Upgren objective prism surveys. The upper panels plot the distribution as a function of distance: the left-hand panel shows the differential number distribution, with the full sample plotted as a solid line and the spectroscopically-identified subset as a dotted line; the right-hand panel shows the fractional contribution from the spectroscopically-selected sample. The predominant contribution of the latter at larger distances is clearly illustrated. The lower panels plot the differential distribution as a function of tangential velocity, with the right-hand panel plotting the fractional contribution from the spectroscopically-selected sample. The horizontal dotted line in the latter panel indicates the fractional contribution of the latter stars to the full sample.

Fig. 5.— The  $(M_V, (B-V))$  colour-magnitude diagram for Hipparcos stars with  $\pi > 40$  mas. The four subdwarfs discussed in the text are plotted as solid triangles, while stars identified as giants or subgiants are plotted as solid points.

Fig. 6.— The  $(M_V, (B-V))$  colour-magnitude diagram after adjusting magnitudes of close binary systems to allow for the contribution from fainter components. Solid squares mark stars in our 25-parsec sample: note that several fall below  $M_V = 8$  after correction for binarity. Other symbols have the same meaning as in Figure 5.

Fig. 7.— The run of density with distance for main-sequence stars with  $4 < M_V < 8$ . The initial point marks the mean density within 16 parsecs for each absolute magnitude interval; subsequent points plot the density within annuli from 16 to 18, 18 to 20, 20 to 22 and 22 to 25 parsecs. There is no evidence for a significant downturn with increasing distance, indicating

a high degree of completeness in the sample.

Fig. 8.— The luminosity function for nearby stars, derived by combining data for the Hipparcos 25-parsec sample and the PMSU sample. Data for single stars and primaries are plotted as solid triangles; the open circles plot the space densities once the appropriate companions are included, with the errorbars reflecting Poisson uncertainties. The solid histogram plots  $\Phi(M_V)$  from Wielen, Jahreiß & Krüger (1983).

Fig. 9.— The Duquennoy & Mayor G-dwarf sample: the lower figure compares the parallaxes listed in the CNS2 catalogue against the Hipparcos data; the upper figure plots the distribution of the stars in the  $(M_V, (B-V))$  plane. Single stars are plotted as solid triangles, binaries as open circles. The photometry of the latter stars has been corrected to exclude contributions from secondary components.

Fig. 10.— The nearby star luminosity function, adjusted to include the contribution from “missing” binary components. The symbols have the same meaning as in Figure 8. As discussed in the text, we have doubled the contribution from known companions to the Hipparcos 25-parsec sample.

Fig. 11.— The  $(M_V, \text{mass})$  relation for main-sequence stars: solid points and open circles plot data for primary and secondary stars, respectively, from Andersen’s compilation of eclipsing binaries; solid triangles plot data for lower main-sequence binaries from Ségransan *et al.* (2000). The five-point star marks the Sun. In the left-hand panel, the long-dashed line shows the empirical fit to the upper main-sequence stars given in the text, the dotted line plots the  $(M_V, \text{mass})$  relation derived by Delfosse *et al.* (2000) and the solid line shows the three-component fit from Henry *et al.* (1993). The right-hand panel compares the former two relations against the KTG semi-empirical relation (solid line).

Fig. 12.— The stellar mass function for the Solar Neighbourhood. The uppermost panel shows the results of applying the mass-luminosity relation to the dataset used to derive  $\Phi(M_V)$  plotted in Figure 8, with the dotted histogram outlining the contribution from single stars and primary stars in binary systems; the middle panel shows  $\xi(M)$  when double weight is given to the Hipparcos 25-parsec secondaries; the lowest panel shows  $\xi(M)$  for the northern 8-parsec sample (Reid *et al.*, 1999). In each case, the dashed lines plot the best-fit power-law (see text).

Fig. 13.— A comparison between the present-day mass function derived using the empirical mass- $M_V$  calibration (upper panel) and the KTG semi-empirical calibration (lower panel). The latter includes the empirical eclipsing-binary relation for  $M_V < 3.5$ . As in Figure 12, the

dotted histogram plots results for single stars/primaries. The main differences lie at near-solar masses, with the semi-empirical calibration showing a steepening at  $\sim 0.7M_{\odot}$  rather than  $\sim 1M_{\odot}$ .

Fig. 14.— The initial mass function: the upper panel shows results based on the empirical mass- $M_V$  relation; the lower plots results using the KTG semi-empirical relation at  $M_V > 3.5$ . The units on the ordinate are surface density, with an arbitrary normalisation. The dashed lines mark the power-law representations described in the text. The solid line and dotted line plot log-normal functions, with the former plotting the best-fit function (see text) and the latter, the original Millar-Scalo function with  $C_1=1.15$ .

Fig. 15.— (U, V, W) diagrams for the VC<sup>2</sup> (right-hand panels) and Hipparcos 25-parsec (left-hand panels) datasets. Solid points mark dMe dwarfs in the VC<sup>2</sup> sample and Hipparcos stars with  $M_V < 4.0$ , respectively.

Fig. 16.— Probability plots for (U, V, W) velocity distributions. The solid line plots data for the full VC<sup>2</sup> sample; the long-dashed lines outline data for the 83 dmE dwarfs in the VC<sup>2</sup> sample; the dotted lines plot the distributions of the Hipparcos faint ( $M_V > 4$ ) sample; and the short-dashed lines plot the bright ( $M_V \leq 4$ ) Hipparcos dataset. The similarity between the full VC<sup>2</sup> and faint Hipparcos datasets is clear.

Fig. 17.— Two-component fits to probability plots of the W velocity distribution of the PMSU VC<sup>2</sup> M dwarf sample (upper plot) and the Hipparcos faint-star sample (lower plot). In both cases, the observations are plotted as a solid line and the low-velocity component is modelled with  $\sigma_W = 16 \text{ km s}^{-1}$ ; the tabulated velocity distributions and relative normalisations refer to the higher-velocity component.

Fig. 18.— The uppermost panel plots the CaH2/TiO5 distribution of the VC<sup>2</sup> M dwarfs (squares), intermediate subdwarfs (sdM - triangles), and extreme subdwarf (esdM - open circles). The solid lines are polynomial relations matched to the first two datasets. The middle panel plots the CaH2 residuals for the VC<sup>2</sup> dwarfs as a function of W velocity; the lower panel plots those residuals normalised to the offset between the mean M dwarf and sdM relations. Neither of the residual plots show evidence for a systematics trend with velocity.

Fig. 1.— A comparison between distance determinations pre- and post-Hipparcos. The upper panel plots the difference,  $\Delta d = d_{PMSU4} - d_{PMSU1}$ , for the 1684 M dwarfs. The lower panel shows the effect on the original VC sample, plotting the revised distances and absolute magnitudes in comparison to the PMSU1 distance limits. 71 of 499 systems fall outwith the formal sampling volume.

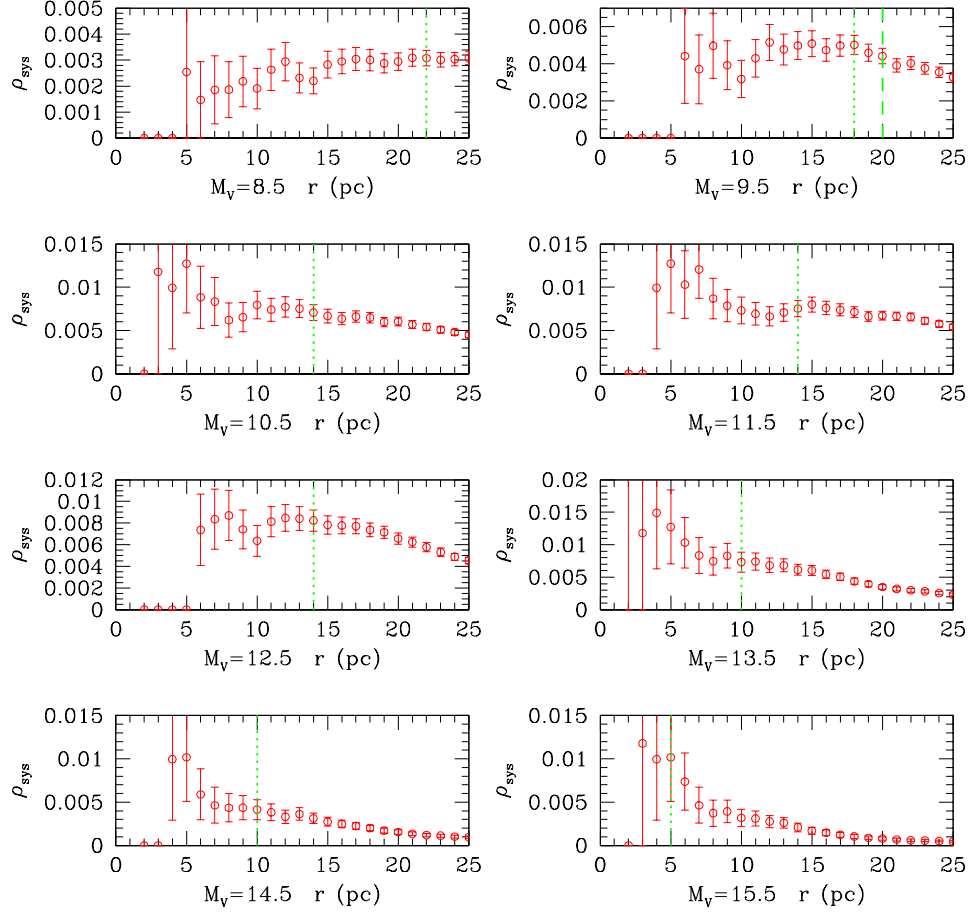

Fig. 2.— The run of density with increasing distance for pCNS3 M dwarfs as a function of absolute magnitude. The dotted vertical lines mark the distance limits for the volume-complete sample; the dashed vertical line for  $M_V=9.5$  marks the value adopted in Paper I.

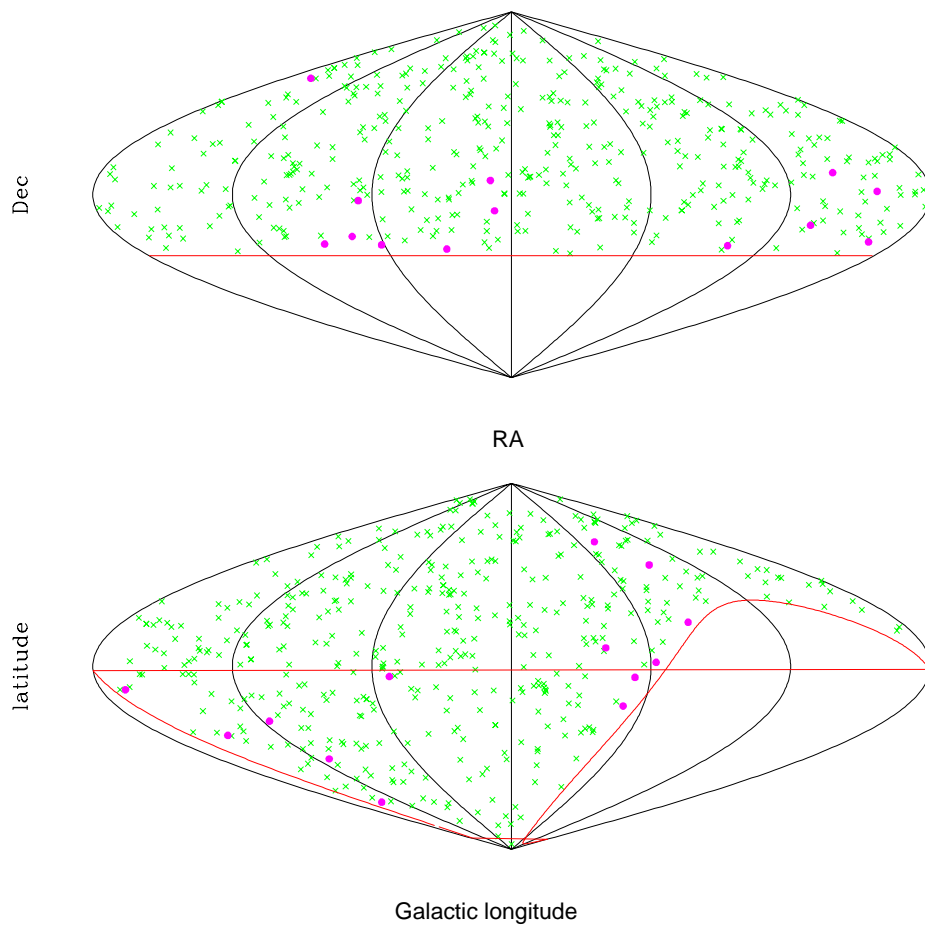

Fig. 3.— The distribution of the VC<sup>2</sup> systems on the celestial sphere, as a function of both equatorial and Galactic co-ordinates. The solid line indicates the  $-30^\circ$  limit in both cases.

Fig. 4.— Comparison between the properties of the full VC<sup>2</sup> sample and the subset of stars identified in the Vyssotsky and Upgren objective prism surveys. The upper panels plot the distribution as a function of distance: the left-hand panel shows the differential number distribution, with the full sample plotted as a solid line and the spectroscopically-identified subset as a dotted line; the right-hand panel shows the fractional contribution from the spectroscopically-selected sample. The predominant contribution of the latter at larger distances is clearly illustrated. The lower panels plot the differential distribution as a function of tangential velocity, with the right-hand panel plotting the fractional contribution from the spectroscopically-selected sample. The horizontal dotted line in the latter panel indicates the fractional contribution of the latter stars to the full sample.

Fig. 5.— The  $(M_V, (B-V))$  colour-magnitude diagram for Hipparcos stars with  $\pi > 40$  mas. The four subdwarfs discussed in the text are plotted as solid triangles, while stars identified as giants or subgiants are plotted as solid points.

Fig. 6.— The  $(M_V, (B-V))$  colour-magnitude diagram after adjusting magnitudes of close binary systems to allow for the contribution from fainter components. Solid squares mark stars in our 25-parsec sample: note that several fall below  $M_V = 8$  after correction for binarity. Other symbols have the same meaning as in Figure 5.

Fig. 7.— The run of density with distance for main-sequence stars with  $4 < M_V < 8$ . The initial point marks the mean density within 16 parsecs for each absolute magnitude interval; subsequent points plot the density within annuli from 16 to 18, 18 to 20, 20 to 22 and 22 to 25 parsecs. There is no evidence for a significant downturn with increasing distance, indicating a high degree of completeness in the sample.

Fig. 8.— The luminosity function for nearby stars, derived by combining data for the Hipparcos 25-parsec sample and the PMSU sample. Data for single stars and primaries are plotted as solid triangles; the open circles plot the space densities once the appropriate companions are included, with the errorbars reflecting Poisson uncertainties. The solid histogram plots  $\Phi(M_V)$  from Wielen, Jahreiβ & Krüger (1983).

Fig. 9.— The Duquennoy & Mayor G-dwarf sample: the lower figure compares the parallaxes listed in the CNS2 catalogue against the Hipparcos data; the upper figure plots the distribution of the stars in the  $(M_V, (B-V))$  plane. Single stars are plotted as solid triangles, binaries as open circles. The photometry of the latter stars has been corrected to exclude contributions from secondary components.

Fig. 10.— The nearby star luminosity function, adjusted to include the contribution from “missing” binary components. The symbols have the same meaning as in Figure 8. As discussed in the text, we have doubled the contribution from known companions to the Hipparcos 25-parsec sample.

Fig. 11.— The  $(M_V, \text{mass})$  relation for main-sequence stars: solid points and open circles plot data for primary and secondary stars, respectively, from Andersen’s compilation of eclipsing binaries; solid triangles plot data for lower main-sequence binaries from Ségresan *et al.* (2000). The five-point star marks the Sun. In the left-hand panel, the long-dashed line shows the empirical fit to the upper main-sequence stars given in the text, the dotted line plots the  $(M_V, \text{mass})$  relation derived by Delfosse *et al.* (2000) and the solid line shows the three-component fit from Henry *et al.* (1993). The right-hand panel compares the former two relations against the KTG semi-empirical relation (solid line).

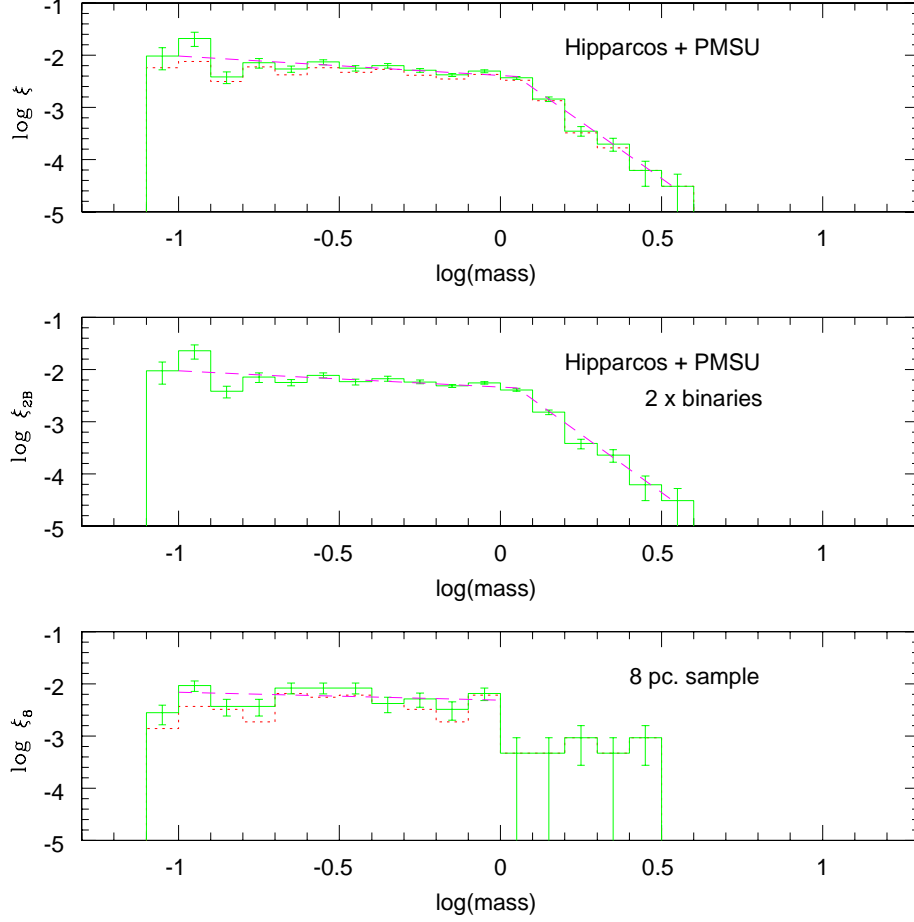

Fig. 12.— The stellar mass function for the Solar Neighbourhood. The uppermost panel shows the results of applying the mass-luminosity relation to the dataset used to derive  $\Phi(M_V)$  plotted in Figure 8, with the dotted histogram outlining the contribution from single stars and primary stars in binary systems; the middle panel shows  $\xi(M)$  when double weight is given to the Hipparcos 25-parsec secondaries; the lowest panel shows  $\xi(M)$  for the northern 8-parsec sample (Reid *et al.*, 1999). In each case, the dashed lines plot the best-fit power-law (see text).

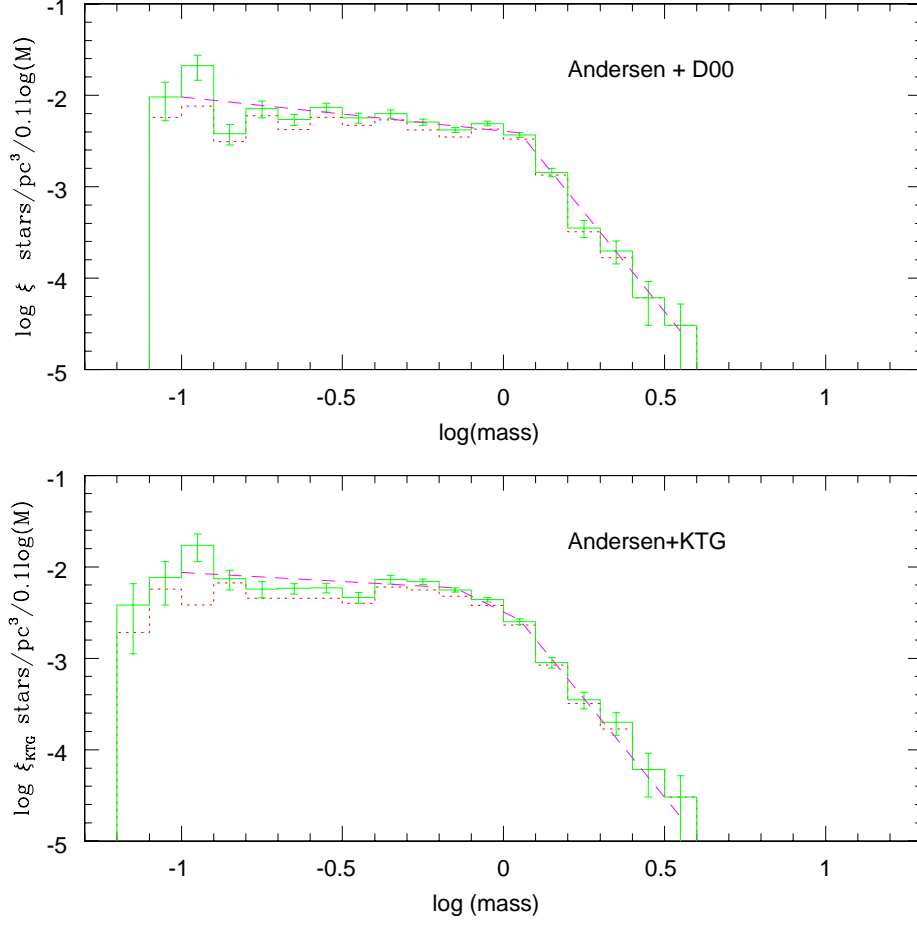

Fig. 13.— A comparison between the present-day mass function derived using the empirical mass- $M_V$  calibration (upper panel) and the KTG semi-empirical calibration (lower panel). The latter includes the empirical eclipsing-binary relation for  $M_V < 3.5$ . As in Figure 12, the dotted histogram plots results for single stars/primaries. The main differences lie at near-solar masses, with the semi-empirical calibration showing a steepening at  $\sim 0.7M_\odot$  rather than  $\sim 1M_\odot$ .

Fig. 14.— The initial mass function: the upper panel shows results based on the empirical mass- $M_V$  relation; the lower plots results using the KTG semi-empirical relation at  $M_V > 3.5$ . The units on the ordinate are surface density, with an arbitrary normalisation. The dashed lines mark the power-law representations described in the text. The solid line and dotted line plot log-normal functions, with the former plotting the best-fit function (see text) and the latter, the original Millar-Scalo function with  $C_1=1.15$ .

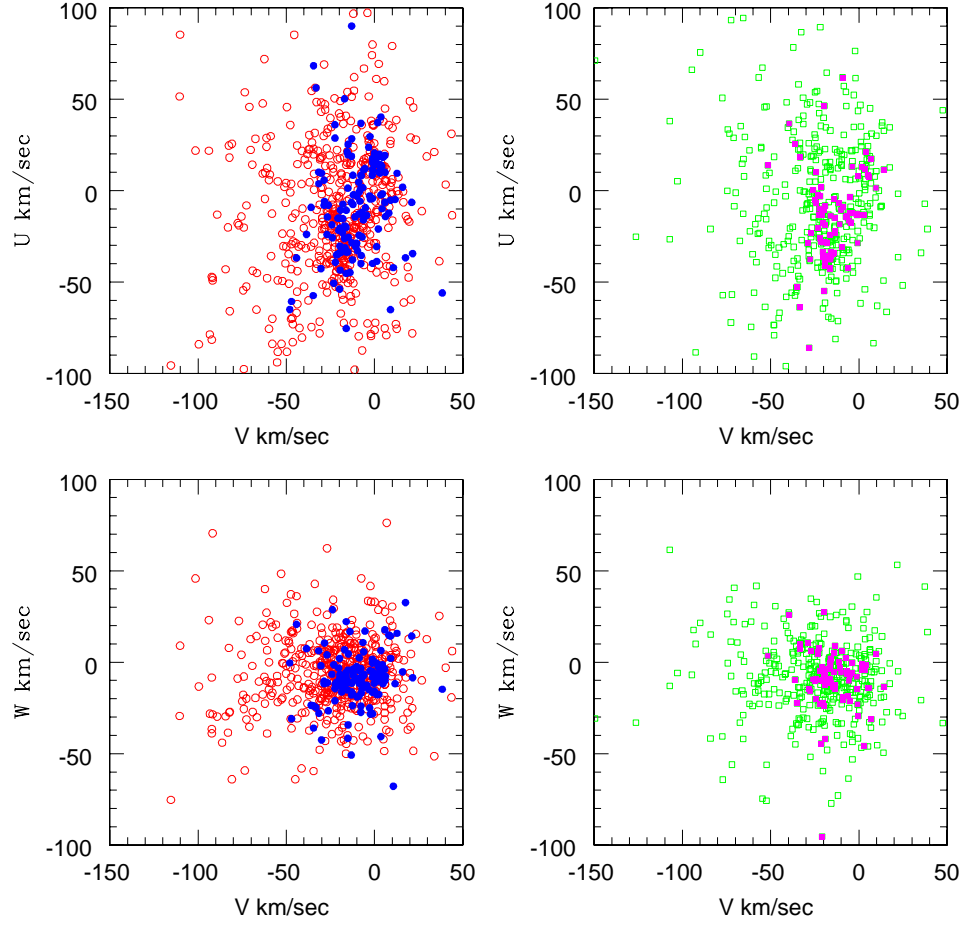

Fig. 15.— (U, V, W) diagrams for the VC<sup>2</sup> (right-hand panels) and Hipparcos 25-parsec (left-hand panels) datasets. Solid points mark dMe dwarfs in the VC<sup>2</sup> sample and Hipparcos stars with  $M_V < 4.0$ , respectively.

Fig. 16.— Probability plots for (U, V, W) velocity distributions. The solid line plots data for the full VC<sup>2</sup> sample; the long-dashed lines outline data for the 83 dmE dwarfs in the VC<sup>2</sup> sample; the dotted lines plot the distributions of the Hipparcos faint ( $M_V > 4$ ) sample; and the short-dashed lines plot the bright ( $M_V \leq 4$ ) Hipparcos dataset. The similarity between the full VC<sup>2</sup> and faint Hipparcos datasets is clear.

Fig. 17.— Two-component fits to probability plots of the W velocity distribution of the PMSU VC<sup>2</sup> M dwarf sample (upper plot) and the Hipparcos faint-star sample (lower plot). In both cases, the observations are plotted as a solid line and the low-velocity component is modelled with  $\sigma_W = 16$  km s<sup>-1</sup> ; the tabulated velocity distributions and relative normalisations refer to the higher-velocity component.

Fig. 18.— The uppermost panel plots the CaH2/TiO5 distribution of the VC<sup>2</sup> M dwarfs (squares), intermediate subdwarfs (sdM - triangles), and extreme subdwarf (esdM - open circles). The solid lines are polynomial relations matched to the first two datasets. The middle panel plots the CaH2 residuals for the VC<sup>2</sup> dwarfs as a function of W velocity; the lower panel plots those residuals normalised to the offset between the mean M dwarf and sdM relations. Neither of the residual plots show evidence for a systematics trend with velocity.
